Sorting and Searching

If you keep proving stuff that others have done, getting confidence, increasing
the complexities of your solutions—for the fun of it—then one day you’ll turn
around and discover that nobody actually did that one! And that’s the way to
become a computer scientist.

Richard Feynman, Lectures on Computation

In this chapter, we conclude the first half of this book by presenting two
extended examples that use the programming techniques from Chapters 2–5 and the analysis ideas from Chapters 6–8 to solve some interesting and
important problems. First, we consider the problem of arranging a list in
order. Next, we consider the problem of finding an item that satisfies some
property.

These examples involve some quite challenging problems and incorporate
many of the ideas we have seen up to this point in the book. Readers who
can understand them well are well on their way to thinking like computer
scientists!

9.1 Sorting

The sorting problem takes two inputs: a list of elements, and a comparison
procedure. The result is a list containing same elements as the input list
ordered according to the comparison procedure. For example, if we sort a
list of numbers using < as the comparison procedure, the output is the list
of numbers sorted in order from least to greatest.

Sorting is one of the most widely studied problems in computing, and
many different sorting algorithms have been developed and analyzed. In
this section, we explore a few sorting procedures. Curious readers should
attempt to develop their own sorting procedures before continuing further.
It may be illuminating to try sorting some items by hand an think carefully
about how you do it and how much work it is. For example, take a shuffled
deck of cards and arrange them in sorted order by ranks. Or, try arranging

all the students in your class alphabetically by name, or chronologically by birthday.

9.1.1 Best-First Sort

A simple sorting strategy is to find the best element in the list and put that at the front. For a given comparison function, the best element is an element for which the comparison procedure evaluates to true when applied to that element and every other element. For example, if the comparison function is $<$, the best element is the smallest number in the list. This element belongs at the front of the output list.

The notion of the best element in the list for a given comparison function only makes sense if the comparison function has the property that for any inputs $a$, $b$, and $c$, if $(c f a) b$ and $(c f c) b$ are both true, the result of $(c f a) c$ must be true. This property is known as transitivity. The $<$ function is transitive: $a < b$ and $b < c$ implies $a < c$ for all numbers $a$, $b$, and $c$. If the comparison function does not have this property, there may be no way to arrange the elements in a single sorted list, so all of our sorting procedures require that the procedure passed as the comparison function is transitive.

Once we can find the best element in a given list, we can sort the whole list by successively finding the best element of the remaining elements until no more elements remain. To define our best-first sorting procedure, we first define a procedure for finding the best element in the list, and then define a procedure for removing an element from a list.

Finding the Best. The best element in the list is either the first element, or the best element from the rest of the list. Hence, we define list-find-best recursively. An empty list has no best element, so the base case is for a list that has one element. When the input list has only one element, then whatever that element is it is the best element in the singleton list. If the list has more than one element, the best element is the better of the first element in the list and the best element of the rest of the list.

To pick the better element from two elements, we define the pick-better procedure that takes three inputs: a comparison function and two values.

\[
\text{define} \ (\text{pick-better} \ cf \ p1 \ p2) \ (\text{if} \ (cf \ p1 \ p2) \ p1 \ p2)\]

Assuming the procedure passed as $cf$ has constant running time, the running time of pick-better is constant. For most of our examples, we use the $<$ procedure as the comparison function. For arbitrary inputs, the running time of $<$ is not constant since in the worst case performing the comparison requires examining every digit in the input numbers. But, if the maximum
value of a number in the input list is limited, then we can consider \(<\) a constant time procedure since all of the inputs passed to it in this context are below some fixed size.

Then, we use \textit{pick-better} to define \textit{list-find-best}:

\begin{verbatim}
(define (list-find-best cf p)
  (if (null? (cdr p))
    (car p)
    (pick-better cf (car p) (list-find-best cf (cdr p)))))
\end{verbatim}

We use \(n\) to represent the number of elements in the input list \(p\). An application of \textit{list-find-best} involves \(n - 1\) recursive applications since each one passes in \((cdr\ p)\) as the new \(p\) operand and the base case stops when the list has one element left. The running time for each application (excluding the recursive application) is constant since it involves only applications of the constant time procedures \textit{null?}, \textit{cdr}, and \textit{pick-better}. So, the total running time for \textit{list-find-best} scales linearly with the length of the input list.

**Deleting an Element.** To implement best first sorting, we need to produce a list that contains all the elements of the original list except for the best element, which will be placed at the front of the output list. We define a procedure, \textit{list-delete}, that takes as inputs a List and a Value, and produces a List that contains all the elements of the input list in the original order except for the first element that is equal to the input value.

\begin{verbatim}
(define (list-delete p el)
  (if (null? p)
    null
    (if (equal? (car p) el); found match, skip this element
      (cdr p)
      (cons (car p) (list-delete (cdr p) el)))))
\end{verbatim}

We use the \textit{equal?} procedure to check if the element matches instead of \(=\), so the \textit{list-delete} procedure works on elements that are not just Numbers. The \textit{equal?} procedure behaves identically to \(=\) when both inputs are Numbers, but also works sensibly on many other datatypes including Booleans, Characters, Pairs, Lists, and Strings. Since we assume the sizes of the inputs to \textit{equal?} are bounded, we can consider \textit{equal?} to be a constant time procedure (even though it would not be constant time on arbitrary inputs).

The worst case running time for \textit{list-delete} occurs when no element in the list matches the value of \(el\) (in the best case, the first element matches and the running time does not depend on the length of the input list at all). We use \(n\) to represent the number of elements in the input list. There can be up to \(n\) recursive applications of \textit{list-delete}. Each application has constant
running time since all of the procedures applied (except the recursive call) have constant running time. Hence, the total running time for list-delete is in $\Theta(n)$ where $n$ is the length of the input list.

**Sorting.** We define list-sort-best-first using list-find-best and list-delete:

```scheme
(define (list-sort-best-first cf p)
  (if (null? p)
      null
    (cons (list-find-best cf p)
          (list-sort-best-first cf (list-delete p (list-find-best cf p))))))
```

The running time of the list-sort-best-first procedure grows quadratically with the length of the input list. We use $n$ to represent the number of elements in the input list. There are $n$ recursive applications since each application of list-delete produces an output list that is one element shorter than its input list. In addition to the constant time procedures (null? and cons), the body of list-sort-best-first involves two applications of list-find-best on the input list, and one application of list-delete on the input list.

As analyzed earlier, each of these applications has running time in $\Theta(m)$ where $m$ is the length of the input list to list-find-best and list-delete (we use $m$ here to avoid confusion with $n$, the length of the first list passed into list-sort-best-first). In the first application, this input list will be a list of length $n$, but in later applications it will be involve lists of decreasing length: $n - 1, n - 2, \ldots, 1$. Hence, the average length of the input lists to list-find-best and list-delete is approximately $m/2$. Thus, the average running time for each of these applications is in $\Theta(\frac{m}{2})$, which is equivalent to $\Theta(n)$.

There are three applications (two of list-find-best and one of list-delete) for each application of list-sort-best-first, so the total running time for each application is in $\Theta(3n)$, which is equivalent to $\Theta(n)$. There are $n$ recursive applications, each with average running time in $\Theta(n)$, so the running time for list-sort-best-first is in $\Theta(n^2)$. This means doubling the length of the input list quadruples the expected running time, so we would expect sorting a list of 2000 elements to take approximately four times as long as sorting a list of 1000 elements.

**Let expression.** Each application of the list-sort-best-first procedure involves two evaluations of (list-find-best cf p), a procedure with running time in $\Theta(n)$ where $n$ is the length of the input list.

The result of both evaluations is the same, so there is no need to evaluate this expression twice. We could just evaluate (list-find-best cf p) once and reuse the result. One way to do this is to introduce a new procedure using a lambda-expression and pass in the result of (list-find-best cf p) as a
parameter to this procedure so it can be used twice:

\[
\text{(define (list-sort-best-first-nodup cf p)}
\begin{align*}
&\text{if (null? p) } \\
&\quad \text{null} \\
&\text{(lambda (best)} \\
&\quad (\text{cons best (list-sort-best-first-nodup cf (list-delete p best))}) \\
&\quad (\text{list-find-best cf p}))
\end{align*}
\]

This procedure avoids the duplicate evaluation of \(\text{(list-find-best cf p)}\), but is quite awkward to read and understand. Scheme provides the let-expression special form to avoid this type of duplicate work more elegantly.

The let-expression is a special form. The grammar for the let-expression is:

\[
\text{Expression} \quad ::= \quad \text{LetExpression} \\
\text{LetExpression} \quad ::= \quad (\text{let (Bindings) Expression}) \\
\text{Bindings} \quad ::= \quad \text{Binding Bindings} \\
\text{Bindings} \quad ::= \quad \epsilon \\
\text{Binding} \quad ::= \quad (\text{Name Expression})
\]

The evaluation rule for the let-expression is:

**Evaluation Rule 6: Let-expression.** To evaluate a let-expression, evaluate each binding in order. To evaluate each binding, evaluate the binding expression and bind the name to the value of that expression. Then, the value of the let-expression is the value of the body expression evaluated with the names in the expression that match binding names substituted with their bound values.

A let-expression can be transformed into an equivalent application expression. The let-expression

\[
\text{(let (\(\text{Name}_1 \text{ Expression}_1\} \\
\quad (\text{Name}_2 \text{ Expression}_2) \\
\quad \ldots \\
\quad (\text{Name}_k \text{ Expression}_k)) \\
\text{Expression}_{\text{body}})}
\]

is equivalent to the application expression:
\[(\texttt{lambda} (\texttt{Name}_1 \texttt{Name}_2 \ldots \texttt{Name}_k)\]
\[\texttt{Expression}_\text{body}\]
\[\texttt{Expression}_1 \texttt{Expression}_2 \ldots \texttt{Expression}_k)\]

The advantage of the let-expression syntax is it puts the expressions next to the names to which they are bound. Using a let-expression, we can define \texttt{list-sort-best-first} to avoid the duplicate evaluations of \texttt{list-find-best} in a way that is easier to read and understand than the application expression:

\[(\texttt{define} \texttt{(list-sort-best-first-let cf} p)\]
\[\texttt{(if} \texttt{(null?}\ p)\]
\[\texttt{null}\]
\[\texttt{(let}}\ ((\texttt{best} \texttt{(list-find-best cf}} p)))\]
\[\texttt{(cons} \texttt{best} \texttt{(list-sort-best-first-let cf} \texttt{(list-delete p best))))))\]

This runs faster than \texttt{list-sort-best-first} since it avoids the duplicate evaluations of \texttt{list-find-best}, but the asymptotic growth rate is the same. The running time of \texttt{list-sort-best-first-let} is in \(\Theta(n^2)\) since there are \(n\) recursive applications of \texttt{list-sort-best-first-let} and each application involves linear time applications of \texttt{list-find-best} and \texttt{list-delete}. It improves the actual running time by avoiding the duplicate work, but does not impact the asymptotic growth rate since the duplicate work is hidden in the constant factor.

\textbf{Exercise 9.1.} Use the \texttt{time} special form (introduced in Chapter 7) to measure the actual evaluation times for applications of the \texttt{list-sort-best-first} procedure. See if the results in your interpreter match the expected running times based on the analysis that the running time of the procedure is in \(\Theta(n^2)\). **Hint:** You may find it helpful to define a procedure that constructs a list containing \(n\) random elements. To generate the random elements use the built-in procedure \texttt{random} that takes one Number as input and evaluates to a random number between 0 and one less than the value of the input Number. Be careful in your time measurements that you do not include the time required to generate the input list.

\textbf{Exercise 9.2.} Compare the running times of the original \texttt{list-sort-best-first} procedure and the \texttt{list-sort-best-first-let} procedure that avoids duplicate work. Are the timing results consistent with the analysis?

\textbf{Exercise 9.3.} [\(\star\)] Define the \texttt{list-find-best} procedure using the \texttt{list-accumulate} procedure from Section 5.4.2 and evaluate its asymptotic running time.
Exercise 9.4. [✓] Instead of sorting the elements by finding the best element first and putting at the front of the list, we could sort by finding the worst element first and putting it at the end of the list. Define a list-sort-worst-last procedure that sorts this way and analyze the running time of your list-sort-worst-last procedure.

9.1.2 Insertion Sort

The list-sort-best-first procedure seems quite inefficient. For every output element, we are searching the whole remaining list to find the best element, but do nothing of value with all the comparisons that were done to find the best element.

An alternate approach is to build up a sorted list as we go through the elements. Insertion sort works by putting the first element in the list in the right place in the list that results from sorting the rest of the elements.

First, we define the list-insert-one procedure that takes three inputs: a comparison procedure, an element, and a List. The input List must be sorted according to the comparison function. As output, list-insert-one produces a List consisting of the elements of the input List, with the input element inserts in the right place according to the comparison function:

\[
\text{(define (list-insert-one cf el p) \; requires: p must be in sorted order by cf)}
\]
\[
\text{(if (null? p)}
\text{  (list el)}
\text{  (if (cf el (car p)}
\text{    (cons el p)}
\text{    (cons (car p) (list-insert-one cf el (cdr p))}))})
\]

The running time for list-insert-one is in $\Theta(n)$ where $n$ is the number of elements in the input list. In the worst case, the input element belongs at the end of the list and we need to make $n$ recursive applications of list-insert-one. Each application involves constant work, so the overall running time of list-insert-one is in $\Theta(n)$.

To sort the whole list, we need to insert each element into the list that results from sorting the rest of the elements:

\[
\text{(define (list-sort-insert cf p)}
\text{  (if (null? p)}
\text{    null)}
\text{    (list-insert-one cf (car p) (list-sort-insert cf (cdr p)))))}
\]
9.1. Sorting

Evaluating an application of list-sort-insert on a list of length \( n \) involves \( n \) recursive applications of list-sort-insert. The lengths of the input lists in the recursive applications are \( n - 1, n - 2, \ldots, 0 \). Each application involves an application of list-insert-one which has running time in \( \Theta(m) \) where \( m \) is the number of elements in the input list to list-insert-one. The average length of the input list over all the applications is approximately \( \frac{n}{2} \), so the average running time of the list-insert-one applications is in \( \Theta(n) \). Since there are \( n \) applications of list-insert-one, the total running time is in \( \Theta(n^2) \).

**Exercise 9.5.** We analyzed the worst case running time of list-sort-insert above. Analyze the best case running time. Your analysis should identify the inputs for which list-sort-insert runs fastest, and describe the asymptotic running time is for the best case input.

**Exercise 9.6.** Both the list-sort-best-first-sort and list-sort-insert procedures have asymptotic running times in \( \Theta(n^2) \). This tells us how their worst case running times grow with the size of the input, but isn’t enough to know which procedure is faster for a particular input. For the questions below, use both analytical and empirical analysis to provide a convincing answer.

a. How do the actual running times of list-sort-best-first-sort and list-sort-insert on typical inputs compare?

b. Are there any inputs for which list-sort-best-first is faster than list-sort-insert?

c. For sorting a long list of \( n \) random elements, how long does each procedure take? (See Exercise 9.1 for help on creating a list of random elements.)

**9.1.3 Quicker Sorting**

Although insertion sort is typically faster than best-first sort, its running time is still scales quadratically with the length of the list. If it takes 100 milliseconds (one tenth of a second) to sort a list containing 1000 elements using list-sort-insert (on my laptop, it takes about 120 milliseconds to sort a random list of 1000 elements), we would expect it to take four (\( = 2^2 \)) times as long to sort a list containing 2000 elements, and a million times (\( = 1000^2 \)) as long (over a day!) to sort a list containing one million (1000 \( \times \) 1000) elements. Yet computers routinely need to sort lists containing many millions of elements (for example, consider processing credit card transactions or analyzing the data collected by a super collider).
Chapter 9. Sorting and Searching

The problem with our insertion sort is that it divides the work unevenly into inserting one element and sorting the rest of the list. This is a very unequal division. Any sorting procedure that works by considering one element at a time and putting it in the sorted position as is done by list-sort-find-best and list-sort-insert will have a running time in \( \Omega(n^2) \). We cannot do better than this with this strategy since there are \( n \) elements, and the time required to figure out where each element goes is in \( \Omega(n) \).

To do better, we need to either reduce the number of recursive applications needed to sort the list (this would mean each recursive call results in more than one element being sorted), or reduce the time required for each application. The approach we take is to use each recursive application to divide the list into two approximately equal-sized parts, but to do the division in such a way that the results of sorting the two parts can be combined directly to form the result. This means, we should partition the elements in the list so that all elements in the first part are less than (according to the comparison function) all elements in the second part.

Our first attempt is to modify insert-one to partition the list into two parts (this approach does not quite produce a sorting procedure with running time in better than \( \Theta(n^2) \) because of the inefficiency of accessing list elements; however, this attempt leads to insights for producing a quicker sorting procedure).

First, we define the list-extract procedure that takes three inputs: a List, and two Numbers indicating the start and end positions. As output, it produces a List consisting of the elements of the input list between the start and end position.

\[
(\text{define } \text{list-extract} p \text{ start end})
(\text{if } (= \text{ start } 0)
  (\text{if } (= \text{ end } 0)
    \text{null}
    (\text{cons} (\text{car} p) (\text{list-extract} (\text{cdr} p) \text{ start } (- \text{ end } 1))))
  (\text{list-extract} (\text{cdr} p) (\text{ start } 1) (\text{ end } 1)))
\]

The running time of the list-extract procedure is in \( \Theta(n) \) where \( n \) is the number of elements in the input list. The worst case input is when the value of end is the length of the input list, which means there will be \( n \) recursive applications, each involving a constant amount of work.

We use list-extract to define procedures for obtaining lists of the first and second halves of the elements of an input list (when the list has an odd number of elements, we put the middle element in the second half of the list).
\begin{verbatim}
(define (list-first-half p)
  (list-extract p 0 (floor (/ (list-length p) 2))))

(define (list-second-half p)
  (list-extract p (floor (/ (list-length p) 2)) (list-length p)))
\end{verbatim}

The \emph{list-first-half} and \emph{list-second-half} procedures apply \emph{list-extract}, so they have running times in $\Theta(n)$ where $n$ is the number of elements in the input list.

Next, we define the \emph{list-insert-one-halves} procedure to only consider the appropriate half of the list.

\begin{verbatim}
(define (list-insert-one-halves cf el p) ; requires: p is sorted by cf
  (if (null? p)
    (list el)
    (if (null? (cdr p))
      (if (cf el (car p)) (cons el p) (list (car p) el))
      (let ((front (list-first-half p))
          (back (list-second-half p)))
        (if (cf el (car back))
          (list-append (list-insert-one-halves cf el front) back)
          (list-append front (list-insert-one-halves cf el back)))))))
\end{verbatim}

In addition to the normal base case when the input list is null, we need a special case when the input list has one element. If the element to be inserted is before this element, the output is produced using \emph{cons}; otherwise, we produce a list of the first (only) element in the list followed by the inserted element.

In the recursive case, we use the \emph{list-first-half} and \emph{list-second-half} procedures to split the input list and bind the results of the first and second halves to the \emph{front} and \emph{back} variables so we do not need to evaluate these expressions more than once.

Since the list passed to \emph{list-insert-one-halves} must be sorted, the elements in \emph{front} are all less than the first element in \emph{back}. Hence, we can determine into which of the sublists contains the element should be inserted using just one comparison: if the element is before the first element in \emph{back} it is in the first half, and we produce the result by appending the result of inserting the element in the front half (the recursive call) with the back half unchanged; if the element is not before the first element in \emph{back}, then it is in the second half, so we produce the result by keeping the front half as it is, and appending it with the result of inserting the element in the back half.

To analyze the running time of \emph{list-insert-one-halves} we determine the num-
ber of recursive calls and the amount of work involved in each application. We use \( n \) to denote the number of elements in the input list. Unlike the other recursive list procedures we have analyzed, the number of recursive applications of \textit{list-insert-one-halves} does not scale linearly with the length of the input list. The reason for this is that instead of using \((\text{cdr } p)\) in the recursive application, \textit{list-insert-one-halves} passes in either the front or back value which is the result of \((\text{first-half } p)\) or \((\text{second-half } p)\) respectively. The length of the list produced by these procedures is approximately \( \frac{1}{2} \) the length of the input list. With each recursive application, the size of the input list is halved. This means, doubling the size of the input list only adds one more recursive application.

Recall that the \textit{logarithm} (\( \log_b \)) of a number \( n \) is the number \( x \) such that \( b^x = n \) where \( b \) is the \textit{base} of the logarithm. If the base is 10, then the value of \( \log_{10} n \) is the number \( x \) such that \( 10^x = n \). For example, \( \log_{10} 10 = 1 \) and \( \log_{10} 1000 = 3 \). In computing, we most commonly encounter logarithms with base 2. Doubling the input value, increases the value of its logarithm base two by one: \( \log_2 2n = 1 + \log_2 n \). This corresponds to the situation with \textit{list-insert-one-halves}, where doubling the size of the input increases the number of recursive applications by one.

Changing the base of a logarithm from \( k \) to \( b \) changes the value by the constant factor (see Section 8.1.1), so inside the asymptotic operators a constant base of a logarithm does not matter. Thus, when the amount of work increases by some constant amount when the input size doubles, we write that the growth rate is in \( \Theta(\log n) \) without specifying the base of the logarithm. Thus, the number of recursive applications of \textit{list-insert-one-halves} is in \( \Theta(\log n) \) since doubling the size of the input requires one more recursive application.

Each application of \textit{list-insert-one-halves} involves an application of \textit{list-append} where the first parameter is either the front half of the list, or the result of inserting the element in the front half of the list. In either case, the length of the list is approximately \( \frac{n}{2} \). The running time of \textit{list-append} is in \( \Theta(m) \) where \( m \) is the length of the first input list. So, the time required for each \textit{list-insert-one-halves} application is in \( \Theta(n) \) where \( n \) is the length of the input list to \textit{list-insert-one-halves}.

The lengths of the input lists to \textit{list-insert-one-halves} in the recursive calls are approximately \( \frac{n}{2}, \frac{n}{4}, \frac{n}{8}, \ldots, 1 \) since the length of the list halves with each call. The summation has \( \log_2 n \) terms, and the sum of the list is \( n \), so the average length input is \( \frac{n}{\log_2 n} \). Hence, the total running time for the \textit{list-append} applications in each application of \textit{list-insert-one-halves} is in \( \Theta(\log_2 n \times \frac{n}{\log_2 n}) = \Theta(n) \).
The analysis of the applications of list-first-half and list-second-half is similar: each requires running time in \( \Theta(m) \) where \( m \) is the length of the input list, which averages \( \frac{n}{\log n} \) where \( n \) is the length of the input list of list-insert-one-halves. Hence, the total running time for list-insert-one-halves is in \( \Theta(n) \).

The list-sort-insert-halves procedure is identical to list-sort-insert (except for calling list-insert-one-halves):

\[
\text{(define (list-sort-insert-halves cf p)}
\begin{align*}
& \quad \text{if (null? p)} \\
& \quad \quad \text{null} \\
& \quad \text{(list-insert-one-halves cf (car p) (list-sort-insert-halves cf (cdr p))))}
\end{align*}
\]

As with list-sort-insert, the list-sort-insert-halves procedure involves \( n \) applications of list-insert-one-halves, and the average length of the input list is \( \frac{n}{2} \). Since list-sort-insert-halves involves \( \Theta(n) \) applications of list-insert-one-halves (with average input list length of \( \frac{n}{2} \)), the total running time for list-sort-insert-halves is in \( \Theta(n^2) \). Because of the cost of evaluating the list-append, list-first-half, and list-second-half applications, the change to splitting the list in halves has not improved the asymptotic performance; in fact, because of all the extra work in each application, the actual running time is most likely higher than it was for list-sort-insert.

The problem with our list-insert-one-halves procedure is that the list-first-half and list-second-half procedures have to cdr down the whole list to get to the middle of the list, and the list-append procedure needs to walk through the entire input list to put the new element in the list. All of these procedures have running times that scale linearly with the length of the input list.

What we need is some way of getting to the middle of the list quickly. With the standard list representation this is impossible: it requires one cdr application to get to the next element in the list, so there is no way to access the middle of the list without using at least \( \frac{n}{2} \) applications of cdr. To do better, we need to change the way we represent our data.

### 9.1.4 Binary Trees

A sorted binary tree is a recursive data structure that has two child nodes, the left and right children, and is itself a node. The data structure we will use is known as a sorted binary tree. While a list provides constant time procedures for accessing the first element and the rest of the elements, a binary tree provides constant time procedures for accessing the root element, the left side of the tree, and the right side of the tree. The left and right sides of the tree are themselves trees. So, like a list, a binary tree is a recursive data structure.

We define a binary tree as:
tree ::= null
tree ::= (make-tree Tree Element Tree)

Whereas we defined a List (in Chapter 5) as:

A List is either (1) null or (2) a Pair whose second cell is a List.

a Tree is defined as:

A Tree is either (1) null or (2) a triple while first and third parts
are both Trees.

The make-tree procedure can be defined using cons to package the three in-
puts into a tree:

(define (make-tree left element right)
  (cons element (cons left right)))

We define selector procedures for extracting the parts of a non-null tree:

(define (tree-element tree) (car tree))
(define (tree-left tree) (car (cdr tree)))
(define (tree-right tree) (cdr (cdr tree)))

The tree-left and tree-right procedures are constant time procedures that
evaluate to the left or right subtrees respectively of a tree.

The tree elements are maintained in a sorted structure. All elements in the
left subtree of a Tree are less than (according to the comparison function)
the value of the root element of the Tree; all elements in the right subtree
of a Tree are greater than or equal to the value of the root element of the
Tree (the result of comparing them with the root element is false). For ex-
ample, here is a sorted binary tree containing 6 elements using < as the
comparison function:

```
    7
   / \
  5   12
 / \
1   6
   \
    17
```
The top node has element value 7, and its left subtree is a tree containing the tree elements whose values are less than 7. The null subtrees are not shown. For example, the left subtree of the element whose value is 12 is null. Note that although there are six elements in the tree, we can reach any element from the top by following at most two branches. By contrast, with a list of six elements, we would need five cdr operations to reach the last element.

*depth* The depth of a tree is the largest number of steps needed to reach any node in the tree starting from the root. The example tree has depth 2, since we can reach every node starting from the root of the tree in two or fewer steps. A tree of depth $d$ can contain up to $2^{d+1} - 1$ elements. One way to see this is from this recursive definition for the maximum number of nodes in a tree:

$$\text{TreeNodes}(d) = \begin{cases} 
1 & : \quad d = 0 \\
\text{TreeNodes}(d - 1) + 2 \times \text{TreeLeaves}(d - 1) & : \quad d > 0
\end{cases}$$

A tree of depth zero has one node. Increasing the depth of a tree by one means we can add two nodes for each leaf node in the tree, so the total number of nodes in the new tree is the sum of the number of nodes in the original tree and twice the number of leaves in the original tree. The maximum number of leaves in a tree of depth $d$ is $2^d$ since each level doubles the number of leaves. Hence, the second equation simplifies to

$$\text{TreeNodes}(d - 1) + 2 \times 2^{d-1} = \text{TreeNodes}(d - 1) + 2^d.$$ 

The value of $\text{TreeNodes}(d - 1)$ is $2^{d-1} + 2^{d-2} + \ldots + 1 = 2^d - 1$. Adding $2^d$ and $2^d - 1$ gives $2^{d+1} - 1$ as the maximum number of nodes in a tree of depth $d$. Hence, a well-balanced tree containing $n$ nodes has depth approximately $\log_2 n$.

The *list-first-half*, *list-second-half*, and *list-append* procedures that had running times in $\Theta(n)$ for the standard list representation can all be implemented with constant running times using the tree representation. For example, *list-first-half* can be implemented using *tree-left* and *list-second-half* can be implemented using *tree-right*. To implement *list-append* requires making a new tree using *make-tree*, which is also a constant time procedure.

The *tree-insert-one* procedure inserts an element in a sorted binary tree:
(define (tree-insert-one cf el tree)
  (if (null? tree)
      (make-tree null el null)
      (if (cf el (tree-element tree))
          (make-tree (tree-insert-one cf el (tree-left tree))
                      (tree-element tree)
                      (tree-right tree))
          (make-tree (tree-left tree)
                      (tree-element tree)
                      (tree-insert-one cf el (tree-right tree))))))

When the input tree is null, the new element is the top element of a new tree whose left and right subtrees are null. Otherwise, the procedure compares the element to insert with the element at the top node of the tree. If the comparison evaluates to true, the new element belongs in the left subtree. The result is a tree where the left tree is the result of inserting this element in the old left subtree, and the element and right subtree are the same as they were in the original tree. For the alternate case, the element is inserted in the right subtree, and the left subtree is unchanged.

Unlike list-insert-one, the tree-insert-one procedure involves only applications of constant time procedures, except for the recursive application. Assuming the tree is well balanced (that is, the left and right subtrees contain the same number of elements), each recursive application halves the size of the input tree so there are approximately \( \log_2 n \) recursive calls. Hence, the running time for using tree-insert-one to insert an element in a well balanced tree is in \( \Theta(\log n) \).

Using tree-insert-one, we can define list-to-sorted-tree, a procedure that takes a comparison function and a List as its inputs, and outputs a sorted binary tree containing the elements in the input list. It works by inserting each element of the list in turn into the sorted tree:

(define (list-to-sorted-tree cf p)
  (if (null? p)
      nil
      (tree-insert-one cf (car p) (list-to-sorted-tree cf (cdr p)))))

Assuming well-balanced trees as above (we revisit this assumption later), the expected running time of list-to-sorted-tree is in \( \Theta(n \log n) \) where \( n \) is the size of the input list. There are \( n \) recursive applications of list-to-sorted-tree since each application uses cdr to reduce the size of the input list by one. Each application involves an application of tree-insert-one (as well as only constant-time procedures), so the expected running time of each application is in \( \Theta(\log n) \). Hence, the total running time for list-to-sorted-tree
is in $\Theta(n \log n)$: there are $n$ applications of \textit{tree-insert-one}, each of which has expected running time in $\Theta(\log n)$.

To use our \textit{list-to-sorted-tree} procedure to perform sorting we need to extract a list of the elements in the tree in the correct order. The leftmost element in the tree should be the first element in the list. Starting from the top node, all elements in its left subtree should appear before the top element, and all the elements in its right subtree should follow it. The \textit{tree-extract-elements} procedure does this:

\begin{verbatim}
(define (tree-extract-elements tree)
 (if (null? tree)
   null
   (list-append (tree-extract-elements (tree-left tree))
     (cons (tree-element tree)
           (tree-extract-elements (tree-right tree))))))
\end{verbatim}

The total number of applications of \textit{tree-extract-elements} is between $n$ (the number of elements in the tree) and $3n$ since there can be up to two null trees for each leaf element (it could never actually be $3n$, but for our asymptotic analysis it is enough to know it is always less than some constant multiple of $n$). For each application, the body applies \textit{list-append} where the first parameter is the elements extracted from the left subtree. The end result of all the \textit{list-append} applications is the output list, containing the $n$ elements in the input tree.

Hence, the total size of all the appended lists is at most $n$, and the running time for all the \textit{list-append} applications is in $\Theta(n)$. Since this is the total time for all the \textit{list-append} applications, not the time for each application of \textit{tree-extract-elements}, the total running time for \textit{tree-extract-elements} is the time for the recursive applications, in $\Theta(n)$, plus the time for the \textit{list-append} applications, in $\Theta(n)$, which is in $\Theta(n)$.

Putting things together, we define \textit{list-sort-tree} by applying \textit{tree-extract-elements} to the result of \textit{list-to-sorted-tree}:

\begin{verbatim}
(define (list-sort-tree cf p)
  (tree-extract-elements (list-to-sorted-tree cf p)))
\end{verbatim}

The total running time for \textit{list-sort-tree} is the running time of the \textit{list-to-sorted-tree} application plus the running time of the \textit{tree-extract-elements} application. The running time of \textit{list-sort-tree} is in $\Theta(n \log n)$ where $n$ is the number of elements in the input list (in this case, the number of elements in $p$), and the running time of \textit{tree-extract-elements} is in $\Theta(n)$ where $n$ is the number of elements in its input list (which is the result of the \textit{list-to-sorted}
tree application, a list containing $n$ elements where $n$ is the number of elements in $p$).

Only the fastest growing term contributes to the total asymptotic running time, so the expected total running time for an application of \textit{list-sort-tree-insert} to a list containing $n$ elements is in $\Theta(n \log n)$. This is substantially better than the previous sorting algorithms which had running times in $\Theta(n^2)$ since logarithms grow far slower than their input. For example, if $n$ is one million, $n^2$ is over 50,000 times bigger than $n \log_2 n$; if $n$ is one billion, $n^2$ is over 33 million times bigger than $n \log_2 n$ since $\log_2 1000000000$ is just under 30. There is no general sorting procedure that has expected running time better than $\Theta(n \log n)$, so there is no algorithm that is asymptotically faster than \textit{list-sort-tree} (in fact, it can be proven that no asymptotically faster sorting procedure exists). There are, however, sorting procedures that may have advantages such as how they use memory which may provide better absolute performance in some situations.

\textbf{Unbalanced Trees}. Our analysis assumes the left and right halves of the tree passed to \textit{tree-insert-one} having approximately the same number of elements. If the input list is in random order, this assumption is likely to be valid: each element we insert has equal probability of going in the left or right half, so the halves contain approximately the same number of elements all the way down the tree. But, if the input list is not in random order this may not be the case.

For example, suppose the input list is already in sorted order. Then, each element that is inserted will be the rightmost node in the tree when it is inserted. For the previous example, this produces the unbalanced tree:

```
1
  5
  6
  7
  12
17
```

This tree contains the same six elements as the earlier example, but because it is not well-balanced the number of branches that must be traversed to
reach the deepest element is 5 instead of 2. Similarly, if the input list is in reverse sorted order, we will have an unbalanced tree where only the left branches are used.

In these pathological situations, the tree effectively becomes a list. The number of recursive applications of \textit{tree-insert-one} needed to insert a new element will not be in $\Theta(\log n)$, but rather will be in $\Theta(n)$. Hence, the worst case running time for \textit{list-sort-tree-insert} is in $\Theta(n^2)$ since the worst case time for \textit{tree-insert-one} is in $\Theta(n)$ and there are $\Theta(n)$ applications of \textit{tree-insert-one}. The \textit{list-sort-tree-insert} procedure has expected running time in $\Theta(n \log n)$ for randomly distributed inputs, but has worst case running time in $\Theta(n^2)$.

\textbf{Exercise 9.7.} Define a procedure \textit{binary-tree-size} that takes as input a binary tree and outputs the number of elements in the tree. Analyze the running time of your procedure.

\textbf{Exercise 9.8.} \([\star]\) Define a procedure \textit{binary-tree-depth} that takes as input a binary tree and outputs the depth of the tree. Recall that the depth of a binary tree is the length of the longest path from the root to any node in the tree. The running time of your procedures should not grow faster than linearly with the number of nodes in the tree.

\textbf{Exercise 9.9.} \([\star\star]\) Define a procedure \textit{binary-tree-balance} that takes as input a sorted binary tree and the comparison function, and outputs a sorted binary tree containing the same elements as the input tree but in a well-balanced tree. The depth of the output tree should be no higher than $\log_2 n + 1$ where $n$ is the number of elements in the input tree.

\subsection*{9.1.5 Quicksort}

Although building and extracting elements from trees allows us to sort with expected time in $\Theta(n \log n)$, the constant time required to build all those trees and extract the elements from the final tree is high.

In fact, we can use the same approach to sort without needing to build trees. Instead, we keep the two sides of the tree as separate lists, and sort them recursively. The key is to divide the list into halves by \textit{value}, instead of by \textit{position}. The values in the first half of the list are all less than the values in the second half of the list, so the lists can be sorted separately.

The \textit{list-quick sort} procedure uses \textit{list-filter} (from Example 5.5) to divide the
input list into sublists containing elements below and above the comparison element, and then recursively applies list-quicksort to sort those sublists.

\begin{verbatim}
(define (list-quicksort cf p)
  (if (null? p)
    null
    (list-append
     (list-quicksort cf (list-filter
                         (lambda (el) (cf el (car p)))
                        (cdr p)))
     (cons (car p)
           (list-quicksort cf (list-filter
                              (lambda (el) (not (cf el (car p))))
                              (cdr p)))))))
\end{verbatim}

This is the famous quicksort algorithm that was invented by Sir C. A. R. (Tony) Hoare while he was an exchange student at Moscow State University in 1959. He was there to study probability theory, but also got a job working on a project to translate Russian into English. The translation depended on looking up words in a dictionary. Since the dictionary was stored on a magnetic tape which could be read in order faster than if it was necessary to jump around, the translation could be done more quickly if the words to translate were sorted alphabetically. Hoare invented the quicksort algorithm for this purpose. A few years later, he worked for Elliot Brothers, a small British computer manufacturer. His first assignment there was to implement a sorting library procedure for a new machine they were developing. Quicksort proved to be faster than the best previously known sorting algorithms, and remains the most widely used sorting algorithm.

As with list-sort-tree-insert, the expected running time for a randomly arranged list is in $\Theta(n \log n)$ and the worst case running time is in $\Theta(n^2)$. In the expected cases, each recursive call halves the size of the input list (since if the list is randomly arranged we expect about half of the list elements are below the value of the first element), so there are approximately $\log n$ expected recursive calls.

Each call involves an application of list-filter, which has running time in $\Theta(m)$ where $m$ is the length of the input list. At each call depth, the total length of the inputs to all the calls to list-filter is $n$ since the original list is subdivided into $2^d$ sublists, which together include all of the elements in the original list. Hence, the total running time is in $\Theta(n \log n)$ in the expected cases where the input list is randomly arranged. As with list-sort-tree-insert, if the input list is not randomly rearranged it is possible that all elements end up in the same partition. Hence, the worst case running time of list-quicksort is still in $\Theta(n^2)$.
Exercise 9.10. Estimate the time it would take to sort a list of one million elements using list-qs.

Exercise 9.11. Both the list-qs and list-sort-tree-insert procedures have expected running times in $\Theta(n \log n)$. How do their actual running times compare?

Exercise 9.12. Is there a best case input for list-qs? Describe it and analyze the asymptotic running time for list-qs on best case inputs.

Exercise 9.13. Instead of using binary trees, we could use ternary trees. A node in a ternary tree has two elements, a left element and a right element, where the left element must be before the right element according to the comparison function. Each node has three subtrees: left, containing elements before the left element; middle, containing elements between the left and right elements; and right, containing elements after the right element. Is it possible to sort faster using ternary trees and with binary trees?

9.2 Searching

Nearly all problems can be thought of a search problems in a broad sense. We can solve any problem by defining the space of possible solutions, and then searching that space to find a correct solution. For example, to solve the pegboard puzzle (Example 5.11) we found a way to enumerate all possible sequences of moves and searched that space to find a winning sequence.

In this section we explore a few specific types of search problems. First, we consider the simple problem of finding an element in a list that satisfies some property. Then, we consider searching for an item in sorted data. Finally, we consider the more specific problem of efficiently searching for documents (such as web pages) that contain some target word.

9.2.1 Unstructured Searching

To search for an item that satisfies an arbitrary property in unstructured data, there is no alternative to testing each element in turn until one that satisfies the property is found. Since we have no more information about the property, there is no way to more quickly find a satisfying element.

The list-search procedure takes as input a matching function and a List, and outputs the first element in the list that satisfies the matching function or
false if there is no satisfying element:¹

\[
\text{(define (list-search ef p)} \\
\text{  (if (null? p))} \\
\text{    false ; Not found} \\
\text{  (if (ef (car p)))} \\
\text{    (car p)} \\
\text{    (list-search ef (cdr p)))))}
\]

Here are some example evaluations of list-search:

\[
> \text{list-search (lambda (el) (= 12 el)) (intsto 10)} \\
false \\
> \text{list-search (lambda (el) (= 12 el)) (intsto 15)} \\
12 \\
> \text{list-search (lambda (el) (> el 12)) (intsto 15)} \\
13
\]

Assuming the matching function has constant running time, the worst case running time of list-search is linear in the size of the input list. The worst case is when there is no satisfying element in the list. If the input list has length \(n\), there are \(n\) recursive calls to list-search, each of which involves only constant time procedures.

Without imposing more structure on the input and comparison function, there is no asymptotically more efficient way to search. In the worst case, we always need to test every element in the input list before concluding that there is no element that satisfies the matching function.

### 9.2.2 Binary Search

If the data to search is structured, it may be possible to find an element that satisfies some property without examining all elements. Suppose the input data is a sorted binary tree, as introduced in Section 9.1.4. Then, with a single comparison we can determine if the element we are searching for would be in the left or right subtree. Instead of eliminating just one element with each application of the matching function as was the case with list-search, with a sorted binary tree a single application of the comparison function is enough to eliminate approximately half the elements from consideration.

¹If the input list contains false as an element, we do not know when the list-search result is false if it means the element is not in the list or the element whose value is false satisfies the property. An alternative would be to produce an error if no satisfying element is found, but this is more awkward when list-search is used by other procedures.
To implement binary-tree-search we need two input procedures, in addition to the sorted binary tree containing the elements. We need one procedure to determine when a satisfying element has been found (we call this the ef procedure, since for many of our searches it is some kind of equality test), and a second procedure, cf, to determine whether the left or right subtree should be searched if the root element does not satisfy the ef procedure. Since cf is used to traverse the tree, the input tree must be sorted by cf.

\[
\text{(define (binary-tree-search ef cf tree) ; requires: tree is sorted by cf)}
\]

\[
\text{(if (null? tree)}
false
\text{(if (ef (tree-element tree))}
\text{(tree-element tree)}
\text{(if (cf (tree-element tree))}
\text{(binary-tree-search ef cf (tree-left tree))}
\text{(binary-tree-search ef cf (tree-right tree)))})
\]

We can search for a number in a sorted binary tree of numbers by using = as the equality function and < as the comparison function (which must be the same as the comparison function used to build the tree).

\[
\text{(define (binary-tree-has-number tree target)}
\text{(if (binary-tree-search (lambda (el) (= target el))}
\text{(lambda (el) (< target el))}
\text{tree)}
\]

\[
true
false)
\]

To analyze the running time of binary-tree-search, we need to determine the number of recursive calls. As with our analysis of list-sort-tree we need to assume the input tree is well-balanced. If not, all the elements could be in the right branch, for example, and binary-tree-search becomes like list-search in the pathological case.

If the tree is well-balanced, each recursive call approximately halves the number of elements in the input tree since it passed in either the left or right subtree. Hence, the number of calls needed to reach a null tree is in Θ(\log n) where n is the number of elements in the input tree. This is the depth of the tree: binary-tree-search traverses one path from the root through the tree until either reaching an element that satisfies the ef function, or reaching a null node.

Assuming the procedures passed as ef and cf have constant running time, the work for each call is constant (except for the recursive call). Hence, the total running time for binary-tree-search is in Θ(\log n) where n is the
number of elements in the input tree. This is a huge improvement over linear searching: with linear search, doubling the number of elements in the input doubles the search time; with binary search, doubling the input size only increases the search time by a constant.

9.2.3 Indexed Search

The limitation of binary search is we can only use is when the input data is already sorted. What if we want to search a collection of documents, such as finding all web pages that contain a given word?

The web visible to search engines currently contains billions of web pages most of which contain hundreds or thousands of words. A linear search over such a vast corpus would be infeasible: supposing each word can be tested in 1 millisecond, the time to search 1 trillion words would be over 30 years!

Providing useful searches over large data sets like web documents requires finding a way to structure the data so it is not necessary to examine all documents to perform a search. One way to do this is to build an index that provides a mapping from words to the documents that contain them. Then, we can build the index once, store it in a sorted binary tree, and use it to perform all the searches. Once the index is built, the work required to perform one search is just the time it takes to look up the target word in the index. If the index is stored as a sorted binary tree, this is logarithmic in the number of distinct words.

Strings. We use the built-in String datatype to represent documents and target words. A String is similar to a List, but specialized for representing sequences of characters. A convenient way to make a String is to just use double quotes around a sequence of characters. For example, "abcd" evaluates to a String containing four characters.

The String data type provides built-in procedures for matching and ordering Strings:

- $\text{string}$=?: String × String → Boolean — true if the input Strings have exactly the same sequence of characters, otherwise false.

- $\text{string}<$?: String × String → Boolean — true if the first input String is lexicographically before the second input String, otherwise false.

There are also built-in procedures for converting between Strings and Lists of characters:
9.2. Searching

- **string->list**: String → List — evaluates to a List of characters corresponding to the characters in the input String.

- **list->string**: List → String — evaluates to a String containing the characters in the input List.

One advantage of using Strings instead of Lists of characters is the String representation of "abcd" displays as a "abcd" which is easier to read than the List representation: (#\a #\b #\c #\d). Another advantage is the built-in procedures for comparing Strings; we could certainly write similar procedures for Lists of characters, but lexicographic ordering is somewhat tricky to get right, so it is better to use the built-in procedures.

**Building the index.** The entries in the index are Pairs of a word (which we will represent as a String), and a list of locations where that word appears in the document set. Each location is a Pair consisting of a document identifier (for web documents, this is the Uniform Resource Locator (URL) that is the address of the web page represented as a String) and a Number identifying the position within the document where the word appears (we label positions as the number of characters in the document before this location).

To build the index, we need to split each document into words, and record the position of each word in the document. The first step is to define a procedure that takes as input a String representing an entire document, and produces a List of (word . position) pairs containing one element for each word in the document. We define a word as a sequence of alphabetic characters; any non-alphabetic character (such as a space, number, or punctuation mark) is treated as a word separator and is not included in the index.

The **text-to-word-positions** procedure takes a String as input and outputs a List of word-position pairs corresponding to each word in the input:
(define (text-to-word-positions s)
  (define (text-to-word-positions-iter p w pos)
    (if (null? p)
      (if (null? w) null (list (cons (list->string w) pos)))
      (if (not (char-alphabet? (car p))) ; finished word
        (if (null? w) ; no current word
          (text-to-word-positions-iter (cdr p) null (+ pos 1))
        (cons (cons (list->string w) pos)
          (text-to-word-positions-iter
            (cdr p)
            null
            (+ pos (list-length w) 1)))))
    (text-to-word-positions-iter
      (cdr p)
      (list-append w (list (char-downcase (car p))))
      pos)))
  (text-to-word-positions-iter (string->list s) null 0))

The inner procedure, text-to-word-positions-iter, takes three inputs: a List of the characters in the document, a List of the characters in the current word, and a Number representing the position in the String where the current word starts. It outputs the List of (word . position) pairs. The value passed in as w can be null, meaning there is no current word. Otherwise, it is a List of the characters in the current word. A word starts when the first alphabetic character is found, and continues until either the first non-alphabetic character or the end of the document. We use char-downcase to convert all letters to their lowercase form, so KING, King, and king all correspond to the same word.

The next step is to build an index from the List of word-position pairs. To enable fast searching, we store the index in a binary tree sorted by the target word. The insert-into-index procedure takes as input an index and a word-position pair and outputs an index consisting of the input index with the input word-position pair added.

The index is represented as a sorted binary tree where each element is a Pair of a word and a List of the positions where that word appears. Each word should appear in the tree only once, so if the word-position Pair to be added corresponds to a word that is already in the index, the position is added to the corresponding list of positions. Otherwise, a new entry is added to the index for the word with a list of positions containing the position as its only element.
(define (insert-into-index index wp)
  (if (null? index)
      (make-tree null (cons (car wp) (list (cdr wp))) null)
    (if (string=? (car wp) (car (tree-element index)))
        (make-tree (tree-left index)
                  (cons (car (tree-element index))
                        (list-append (cdr (tree-element index))
                                   (list (cdr wp)))))
       (tree-right index))
    (if (string<? (car wp) (car (tree-element index)))
        (make-tree (insert-into-index (tree-left index) wp)
                  (tree-element index)
                  (tree-right index))
       (make-tree (tree-left index)
                  (tree-element index)
                  (insert-into-index (tree-right index) wp)))))

To insert all the (word . position) pairs in a list into the index, we use insert-into-index to add each pair, passing the resulting index into the next recursive call:

(define (insert-all-wps index wps)
  (if (null? wps)
      index
      (insert-all-wps (insert-into-index index (car wps)) (cdr wps))))

To add all the words in a document to the index we use text-to-word-positions to obtain the list of word-position pairs. Since we want to include the document identity in the positions, we use list-map to add the url (a String that identifies the document location) to the position of each word. Then, we use insert-all-wps to add all the word-position pairs in this document to the index. The index-document procedure takes a document identifier and its text as a String, and produces an index of all words in the document.

(define (index-document url text)
  (insert-all-wps null
     (list-map (lambda (wp) (cons (car wp) (cons url (cdr wp))))
               (text-to-word-positions text))))

We leave analyzing the running time of index-document as an exercise. The important point, though, is that it only has to be done once for a given set of documents. Once the index is built, we can use it to answer any number of search queries without needing to reconstruct the index. Large search
engine companies dedicate large numbers of machines to maintaining the index as new web pages are found.

**Merging indexes.** Our goal is to produce an index for a set of documents, not just a single document. So, we need a way to take two indexes produced by index-document and combine them into a single index. Then, we can use this repeatedly to create an index of any number of documents. To merge two indexes, we need to combine their word occurrences. If a word occurs in both documents, the word should appear in the merged index with a position list that includes all the positions in both indexes. If the word occurs in only one of the documents, that word and its position list should be included in the merged index.

```scheme
(define (merge-indexes d1 d2)
  (define (merge-elements p1 p2)
    (if (null? p1)
        p2
      (if (null? p2)
          p1
        (if (string=? (car p1) (car p2))
            (cons (cons (car (car p1))
                          (list-append (cdr (car p1)) (cdr (car p2))))
                  (merge-elements (cdr p1) (cdr p2)))
            (if (string<? (car p1) (car p2))
                (cons (car p1) (merge-elements (cdr p1) p2))
              (cons (car p2) (merge-elements p1 (cdr p2))))))
    (list-to-sorted-tree
     (lambda (e1 e2) (string<? (car e1) (car e2)))
     (merge-elements (tree-extract-elements d1)
                    (tree-extract-elements d2)))))
```

To merge the indexes, we first use *tree-extract-elements* to convert the tree representations to lists. The inner *merge-elements* procedure takes the two Lists of word-position Pairs and outputs a single List.

Since the lists are sorted by the target word, we can perform the merge efficiently. If the first words in both lists are the same, we produce a word-position pair that appends the position lists for the two entries. If they are different, we use *string<?* to determine which of the words belongs first, and include that element in the merged list. This way, the two lists are kept synchronized, so there is no need to search the lists to see if the same word appears in both lists.

**Obtaining documents.** To build a useful index for searching, we need some documents to index. The web provides a useful collection of freely
available documents. To read documents from the web, we use library procedures provided by DrScheme.

This expression loads the libraries for managing URLs and getting files from the network:

\[(\textit{require (lib "url.ss" "net")})\]

One procedure this library defines is \textit{string->url}, which takes a String as input and produces a representation of that String as a URL. A Uniform Resource Locator (URL) is a standard way to identify a document on the network. The address bar in most web browsers typically displays the URL of the currently displayed web page.

The full grammar for URLs is quite complex, but we will use simple web page addresses of the form:\footnote{We use Name to represent sequences of characters in the domain and path names, although the actual rules for valid names for each of these are different.}

\[
\begin{align*}
\text{URL} & :\Rightarrow \text{http://Domain OptPath} \\
\text{Domain} & :\Rightarrow \text{Name MoreDomain} \\
\text{MoreDomain} & :\Rightarrow . \text{Domain} \\
\text{MoreDomain} & :\Rightarrow e \\
\text{OptPath} & :\Rightarrow \text{Path} \\
\text{OptPath} & :\Rightarrow e \\
\text{Path} & :\Rightarrow / \text{Name OptPath}
\end{align*}
\]

An example of a URL is http://www.whitehouse.gov/index.html. The http indicates the HyperText Transfer Protocol, which prescribes how the web client (browser) and server communicate with each other. The domain name is www.whitehouse.gov, and the path name is /index.html (which is the default page for most web servers).

The library also defines the \textit{get-pure-port} procedure which takes as input a URL and produces a Port for reading the document at that location. The \textit{read-char} procedure takes as input a Port, and outputs the first character in that Port. It also has a side-effect: it advances the Port to the next character. We can use \textit{read-char} repeatedly to read each character in the web page of the Port. When the end of the file is reached, the next application of \textit{read-char} outputs a special marker representing the end of the file. The procedure \textit{eof-object?} evaluates to true when applied to this marker, and false for all other inputs.

The \textit{read-all-chars} procedure takes a Port as its input, and produces a List containing all the characters in the document the Port is associated with:
(define (read-all-chars port)
  (let ((c (read-char port)))
    (if (eof-object? c)
        null
        (cons c (read-all-chars port)))))

Using these procedures, we define web-get, a procedure that takes as input a String that represents the URL of some web page, and produces as output a String representing the contents of that page.

(define (web-get url)
  (list->string (read-all-chars (get-pure-port (string->url url))))))

To make it easy to build an index of a set of web pages, we define the index-pages procedure that takes as input a List of web pages and outputs an index of the words in those pages. It recurses through the list of pages, indexing each document, and merging that index with the result of indexing the rest of the pages in the list.

(define (index-pages p)
  (if (null? p)
      null
      (merge-indexes (index-document (car p) (web-get (car p)))
                      (index-pages (cdr p)))))

We can use this to create an index of any set of web pages. For example, here we use Jeremy Hylton's collection of the complete works of William Shakespeare (http://shakespeare.mit.edu) to define shakespeare-index as an index of the words used in all of Shakespeare's plays.

(define shakespeare-index
  (index-pages
   (list-map
    (lambda (play)
      (string-append "http://shakespeare.mit.edu/" play "/full.html"))
    (list "allswell" "asyoulikeit" "comedy_errors" "cymbeline" "lll"
          "measure" "merry_wives" "merchant" "midsummer" "much_ado"
          "pericles" "taming_shrew" "tempest" "troylus_cressida" "twelfth_night"
          "two_gentlemen" "winters_tale" "1henryiv" "2henryv" "henryv"
          "1henryvi" "2henryvi" "3henryvi" "henryvii" "john" "richardii"
          "richardii" "cleopatra" "coriolanus" "hamlet" "julius_caesar" "lear"
          "macbeth" "othello" "romeo_juliet" "timon" "titus"))))

Building the index takes about two and a half hours on my laptop. It contains 22949 distinct words and over 1.6 million word occurrences. Much of
the time spent building the index is in constructing new lists and trees for every change, which can be avoided by using the mutable data types we cover in the next chapter. The key idea, though, is that the index only needs to be built once. Once the documents have been indexed, we can use the index to quickly perform any search.

**Searching.** Now that we have an index, searching for pages that use a given word is easy and efficient. Since the index is a sorted binary tree, the binary-tree-search procedure does what we need. We just need to pass in procedures for testing if the target word has been found, and for using the lexicographic ordering of the tree to determine whether the target word would be in the left or right subtree. The search-in-index procedure takes as input an index and a String representing the target word, and outputs the entry in the index that corresponds to the target word or false if the target word does not appear in the index.

```
(define (search-in-index index word)
  (binary-tree-search
   (lambda (el) (string=? word (car el)))
   (lambda (el) (string<? word (car el)))
   index))
```

As analyzed in the previous section, the expected running time of binary-tree-search is in $\Theta(\log n)$ where $n$ is the number of nodes in the input tree.\(^3\) The body of search-in-index applies binary-tree-search to the index. The number of nodes in the index is the number of distinct words in the indexed documents. So, the running time of search-in-index scales logarithmically with the number of distinct words in the indexed documents. Note that the number and size of the documents does not matter! This is why a search engine such as Google can respond to a query quickly even though its index contains many billions of documents.

One minor issue we should be careful about is the running time of the procedures passed into binary-tree-search. Our analysis of binary-tree-search requires that the equality and comparison functions are constant time procedures. Here, the procedures as string=? and string<?, which both have worst case running times that are linear in the length of the input string. As used here, one of the inputs is the target word. So, the amount of work for each binary-tree-search recursive call is in $\Theta(w)$ where $w$ is the length of word. Thus, the overall running time of search-in-index is in $\Theta(w \log d)$ where $w$ is the length of word and $d$ is the number of words in the index. If we assume all words are of some maximum length, though, the $w$ term

---

\(^3\)Because of the way merge-indexes is defined, we do not actually get this expected running time. See Exercise 9.16.
Chapter 9. Sorting and Searching

disappears as a constant factor (that is, we are assuming \( w < C \) for some constant \( C \). Thus, the overall running time is in \( \Theta(\log d) \).

Here are some example uses of search-in-index using our index of Shakespeare's plays:

\[
> \text{(search-in-index shakespeare-index "mathematics")}
\]

("mathematics"

("http://shakespeare.mit.edu/taming_shrew/full.html" . 26917)

("http://shakespeare.mit.edu/taming_shrew/full.html" . 75069)

("http://shakespeare.mit.edu/taming_shrew/full.html" . 77341))

> (search-in-index shakespeare-index "procedure")
false

> (search-in-index shakespeare-index "abstraction")
false

Our search-in-index and index-pages procedures form the beginnings of a search engine service. A useful web search engine needs at least two more capabilities: a way to automate the process of finding documents to index, and a way to rank the documents that contain the target word by the likelihood they are useful. The two explorations at the end of this section explore how to provide these capabilities.

Histogram. We can also use our index to answer various interesting questions about Shakespeare's writing. For example, the procedure index-histogram produces a list of the words in an index sorted by how frequently they appear.

\[
\text{(define (index-histogram index)}
\]

(list-quicksort

(lambda (e1 e2) (> (cdr e1) (cdr e2)))

(list-map (lambda (el) (cons (car el) (length (cdr el))))

(tree-extract-elements index))))

The expression

\[
\text{(list-filter (lambda (entry) (> string-length (car entry) 5))}
\]

(index-histogram shakespeare-index))

Evaluates to a list of Shakespeare's favorite 6-letter and longer words:
The first two are words from the web page formatting markup, not from Shakespeare's writing. The rest of the word frequencies provide a glimpse into Shakespeare's world.

**Exercise 9.14.** Define a procedure for finding the longest word in a document. Analyze the running time of your procedure.

**Exercise 9.15.**[*] Analyze the running time required to build the index.

a. Analyze the running time of the `text-to-word-positions` procedure. Use \( n \) to represent the number of characters in the input String, and \( w \) to represent the number of distinct words. Be careful to clearly state all assumptions on which your analysis relies.

b. Analyze the running time of the `insert-into-index` procedure.

c. Analyze the running time of the `index-document` procedure.

d. Analyze the running time of the `merge-indexes` procedure.

e. Analyze the overall running time of the `index-pages` procedure. Your result should describe how the running time is impacted by the number of documents to index, the size of each document, and the number of distinct words.
Exercise 9.16. [⋆] The search-in-index procedure does not actually have the expected running time in $\Theta(\log w)$ (where $w$ is the number of distinct words in the index) for the Shakespeare index because of the way it is built using merge-indexes. The problem has to do with the running time of the binary tree on pathological inputs. Explain why the input to list-to-sorted-tree in the merge-indexes procedure leads to a binary tree where the running time for searching is in $\Theta(w)$. Modify the merge-indexes definition to avoid this problem and ensure that searches on the resulting index run in $\Theta(\log w)$.

Exploration 9.1: Web Crawling

For our Shakespeare index example, we manually found a list of interesting documents to index. This approach does not scale well to indexing the World Wide Web where there are trillions of documents and new ones are created all the time. For this, we need a web crawler.

A web crawler finds documents on the web to add to a search index. Typical web crawlers start with a set of seed URLs, and then find more documents to index by following the links on those pages. This proceeds recursively: the links on each newly discovered page are added to the set of URLs for the crawler to index. To develop a web crawler, we need a way to extract the links on a given web page, and to manage the set of pages to index.

a. [⋆] Define a procedure extract-links that takes as input a String representing the text of a web page and outputs a List of all the pages linked to from this page. Linked pages can be found by searching for anchor tags on the web page. An anchor tag has the form: $<a \text{href=\text{target}}>$.
(The text-to-word-positions procedure may be a helpful starting point for defining extract-links.)

b. [⋆] Define a procedure crawl-page that takes as input an index and a String representing a URL. As output, it produces a pair consisting of an index (that is the result of adding all words from the page at the input URL to the input index) and a List of URLs representing all pages linked to by the crawled page.

c. [★★] Define a procedure crawl-web that takes as input a List of seed URLs and a Number indicating the maximum depth of the crawl. It should output an index of all the words on the web pages at the locations given by the seed URLs and any page that can be reached from these seed URLs by following no more than the maximum depth number of links.

---

4Not all links match this structure exactly, so this may miss some of the links on a page.
9.2. Searching

Explanation 9.2: Ranking Pages

For a web search engine to be useful, we don't want to get all the pages that contain some target word, we want to get a few pages that contain the target word that are the pages that are most likely to be interesting. Selecting the best pages for a given query is a challenging and important problem, and the ability to do this well is one of the main things that distinguishes successful and unsuccessful commercial web search engines. Many factors are used to rank pages including an analysis of the text on the page itself, whether the target word is part of a title, how recently the page was updated, etc.

The most interesting ways of ranking pages also consider the pages that link to the ranked page. If many pages link to a given page, it is more likely that the given page is useful. This property can also be defined recursively: a page is highly ranked if there are many highly-ranked pages that link to it.

The ranking system used by Google is based on this formula:

$$R(u) = \sum_{v \in L_u} \frac{R(v)}{L(v)}$$

where $L_u$ is the set of web pages that contain links to the target page $u$ and $L(v)$ is the number of links on the page $v$ (thus, the value of a link from a page containing many links is less than the value of a link from a page containing only a few links). The value $R(u)$ gives a measure of the ranking of the page identified by $u$, where higher values indicate more valuable pages.

The problem with this formula is that is is circular: there is no base case, and no way to order the web pages to compute the correct rank of each page in turn, since the rank of each page depends on the rank of the other pages that link to it.

One way to approximate equations like this one is to use relaxation. Relaxation obtains an approximate solution to some systems of equations by repeatedly evaluating the equations. To estimate the page ranks for a set of web pages, we initially assume every page has rank 1 and evaluate $R(u)$ for all the pages (using the value of 1 as the rank for every other page). Then, re-evaluate the $R(u)$ values using the resulting ranks. A relaxation keeps repeating until the values stop changing by some threshold amount, but there is no guarantee how quickly this will happen. For the page ranking evaluation, it may be enough to decide on some fixed number of iterations and use the ranks resulting from the last iteration as the final ranks.
Chapter 9. Sorting and Searching

a. Define a procedure, web-link-graph, that takes as input a set of URLs and produces as output a graph of the linking structure of those documents. The linking structure can be represented as a List where each element of the List is a pair of a URL and a List of all the URLs that include a link to that URL. The extract-links procedure from the previous exploration will be useful for determining the link targets of a given URL.

b. Define a procedure that takes as input the output of web-link-graph and outputs a preliminary ranking of each page that measures the number of other pages that link to that page.

c. Refine your page ranking procedure to weight links from highly-ranked pages more heavily in a page's rank by using an algorithm.

d. Come up with a cool name, set up your search engine as a web service, and attract more than 0.001% of all web searches to your site.

---

Exploration 9.3: Historical Histograms

The site http://www.speechwars.com provides an interesting way to view political speeches by looking at how the frequency of the use of different words changes over time. For example, we can see that “computer” was first used in a state of the union speech by Jimmy Carter in 1981, and used five times by Bill Clinton, but not (yet) by any other president. Use the index-histogram procedure to build a historical histogramming program. It could take as input a List of indexes ordered by time, and a target word, and output a List showing the number of occurrences of the target word in each of the indexes. You could use your program to analyze how Shakespeare’s word use is different in tragedies and comedies, how language on the web has changed over time (see http://www.archive.org for a way to obtain snapshots of web pages at particular times in the past), or how some other interesting set of documents evolved over time.

---

9.3 The Story So Far

Chapters 1–9 have introduced several of the most important concepts in computing. Much of what we have seen so far (and much of all of computer science) stems from the three powerful ideas introduced in Section 1.4: recursive definitions, higher order procedures, and abstraction. Here, we recap these ideas, review the many forms in which these ideas have appeared so far, and preview how they will recur later.
Recursive definitions. A recursive definition defines something in terms of a smaller instance of itself and a base case. All interesting languages involve some recursive definitions, since this is the way to produce infinitely many different surface forms from a finite number of rules. Nearly all of the interesting procedures in this book are recursively defined. Datatypes can also be defined recursively, for example a List is either null or a Pair whose second cell is a List. In Part III, we will see many more recursive definitions, and extend the notion of recursive definitions to the language interpreter itself.

Higher order procedures. A procedure defines a precise sequence of steps. Procedures can take inputs that specialize the steps they produce to a particular instance of a problem. Procedures can be passed as inputs to other procedures to enable one procedure to do many different things, and can be produced as outputs of a procedure. In Part III, we will change the language evaluation rules themselves, and see how different evaluation rules enable different ways of expressing procedures. In Part IV, we will extend the notion of procedure to allow a procedure input that can describe any computing machine. Making the input to a procedure a description of an arbitrary computing machine enables us to understand deep properties about what problems can and cannot be solved by mechanical computing.

Abstraction. We use abstraction to represent many different things with one thing so that it is easier to understand and reason about designs. We have seen many different types of abstraction so far: the digital abstraction uses a continuous range of voltages to represent just two values; procedural abstraction defines a procedure using a small amount of code to produce many different processes; and data abstraction hides how data is represented so programmers can focus on what you can do with the data instead of the details of how it is represented. The asymptotic operators used to describe running times are also a kind of abstraction—they allow us to represent the set of infinitely many different functions with a compact notation. In Part III, we will see many more examples of procedural abstraction and data abstraction; we will also develop object abstractions where code and data are packaged into one entity.

Reasoning about computing. The focus of Part II has been on predicting properties of procedures, in particular how their running time scales with the size of their input. With the analysis tools from Chapters 6–8, it is possible to analyze the running time of any procedure.

In Part IV, we consider a deeper problem: what is the running time of the fastest possible algorithm that solves a given problem. Exploring this will allow us to understand what problems can realistically be solved by computers, and what problems it is infeasible to solve with even much more
powerful computers than we have today.

As inventor of Quicksort, Sir Tony gets the last word:

I quickly learned that the characteristic of a good course lasting one term is that after the first half of the course, the students just can’t see what it is about at all, but at the end of the course they can’t see what they found difficult anymore. So you have to choose a fixed time frame, and if you don’t have that initial confusion and doubt you’re probably not teaching things that are stretching your students enough.

Tony Hoare, Charles Babbage Institute Interview, July 2002

We’ve covered a lot of material! Don’t despair if it doesn’t all make sense yet. The same concepts will recur frequently in the remainder of this book, and it takes lots of practice and many years to fully understand the implications of recursive definitions, higher order procedures, and abstraction.
